Ideal triangulations of 3–manifolds I:
spun normal surface theory

Ensil Kang

J Hyam Rubinstein

Abstract In this paper, we will compute the dimension of the space of spun and ordinary normal surfaces in an ideal triangulation of the interior of a compact 3–manifold with incompressible tori or Klein bottle components. Spun normal surfaces have been described in unpublished work of Thurston. We also define a boundary map from spun normal surface theory to the homology classes of boundary loops of the 3–manifold and prove the boundary map has image of finite index. Spun normal surfaces give a natural way of representing properly embedded and immersed essential surfaces in a 3–manifold with tori and Klein bottle boundary [10], [11]. It has been conjectured that every slope in a simple knot complement can be represented by an immersed essential surface [1], [2]. We finish by studying the boundary map for the figure-8 knot space and for the Gieseking manifold, using their natural simplest ideal triangulations. Some potential applications of the boundary map to the study of boundary slopes of immersed essential surfaces are discussed.

Keywords Normal surfaces, 3–manifolds, ideal triangulations

This paper is dedicated to Andrew Casson with thanks for his many wonderful mathematical ideas

1   Introduction

In a series of papers, starting with this one, we will investigate ideal triangulations of the interiors of compact 3-manifolds with incompressible tori or Klein bottle boundaries. Such triangulations have been used with great effect, following the pioneering work of Thurston [17]. Ideal triangulations are the basis of the computer program SNAPPEA of Weeks [4] and the program SNAP of

Coulson, Goodman, Hodgson and Neumann [5]. Casson has also written a program to find hyperbolic structures on such 3-manifolds, by solving Thurston's hyperbolic gluing equations for ideal triangulations.

In the second paper, we will study the problem of deforming a taut triangulation [15] to an angle structure. We show that given a taut ideal triangulation of the interior of a compact 3-manifold with tori or Klein bottle boundary components, which is irreducible, $\mathbb{P}^2$-irreducible and atoroidal with no 2-sided Klein bottles or Mobius bands, there are angle structures if and only if a certain combinatorial obstruction vanishes. This work is inspired by ideas of Casson. In the third paper, various connections between structures on ideal triangulations will be examined in the case of small numbers of tetrahedra. In the fourth paper, a theory of immersed normal and spun normal surfaces in ideal triangulations with angle structures will be studied. In the fifth paper, we show that immersed essential surfaces can be homotoped to be spun normal, in case the surfaces do not lift to fibres of bundles in finite sheeted covers. Examples are given of different triangulations of bundles, where such fibres can and cannot be realised by spun normal surfaces. Moreover, a very fast algorithm to decide if a given embedded normal surface is incompressible is given, using these ideas.

In this paper, for simplicity, all 3-manifolds M will be the interior of a compact manifold N with tori or Klein bottle boundary components. We will work in the smooth category. All 3-manifolds will be irreducible and $\mathbb{P}^2$-irreducible, i.e every embedded 2-sphere bounds a 3-ball and there are no embedded 2-sided projective planes. For basic 3-manifold theory, see either [7] or [8].

An ideal triangulation Γ of M will be a cell complex which is a decomposition of M into tetrahedra $\Delta_1, \Delta_2, ..., \Delta_k$ glued along their faces and edges, so that the vertices of the tetrahedra are all removed. Moreover the link of each such missing vertex will be a Klein bottle or torus. Note that several vertices, edges or faces of a tetrahedron may be identified. (Sometimes such triangulations are called pseudo-triangulations.) Using Moise's construction of triangulations of 3–manifolds [16], one can convert a triangulation of N into such an ideal triangulation, by collapsing the boundary surfaces to ideal vertices and also collapsing edges which join the ideal vertices to the interior vertices. See [9] for a discussion of such collapsing procedures. One has to be careful to ensure that at each stage of such collapsings the topological type of M is not changed.

Alternatively one can collapse M onto a 2–dimensional spine $\mathcal{S}$ and then choose a dual triangulation. Assume that M has at least two boundary components. A convenient way to do this is to choose a Heegaard splitting, ie a decomposition of N into compression bodies X, Y so that these are glued along a Heegaard

surface S. X, Y are obtained from $S \times I$ by gluing 2–handles to $S \times \{1\}$ (S can be non-orientable or orientable). We can arrange that S has boundary components of N on either side of it. Then the common boundary surface S of the compression bodies is obtained by gluing the two copies of $S \times \{0\}$. Now if a collection of core disks for the 2–handles for X, Y is attached to S, we get the required spine $\mathcal{S}$ for M and N. It is straightforward to check that the dual cell structure to this spine is an ideal triangulation for M. If M has only one boundary component, then the same procedure will construct a triangulation of M with one ideal vertex and one vertex in the interior of M. We then (carefully) collapse an edge joining these two vertices as in [9] to get an ideal triangulation.

We now summarize Haken's theory of normal surfaces [6], as extended by Thurston to deal with spun normal surfaces in ideal triangulations. Given an abstract tetrahedron Δ with vertices $ABCD$, there are four normal triangular disk types, cutting off small neighborhoods of each of the four vertices. There are also three normal quadrilateral disk types, which separate pairs of opposite edges, such as AB, CD. Each tetrahedron Δ_i of Γ contributes 7 coordinates which are the numbers n_j of each of the normal disk types. We can form a vector of length $7k$ from all of these coordinates n_j, $1 \le j \le 7k$ and a normal surface S is formed by gluing finitely many normal disk types together. There are $6k$ compatibility equations, each of the form $n_i + n_j = n_m + n_p$, where the left side of the equation gives the number of normal triangles and quadrilaterals with a particular normal arc type in the boundary, eg the arc running between edges AB, AC in Δ. If the face ABC is glued to $A'B'C'$ of the tetrahedron Δ', then n_m, n_p are the number of normal triangles and quadrilaterals with the boundary normal arc type running between $A'B', A'C'$ in Δ'. Note that we allow self-identifications of tetrahedra and hence also of normal disk types.

It turns out that the solution space $\mathcal{V}$ of these compatibility equations in $\mathbb{R}^{7k}$ has dimension $2k$, ie there are k redundant compatibility equations. The non-negative integer solutions in $\mathcal{V}$ then give normal surfaces (possibly non-uniquely) and we can regard $2k$ as the dimension of the space of these surfaces. We will give a proof of this in the next section, as it is important in computing the dimension of the space $\mathcal{W}$ of spun and ordinary normal surfaces. In fact, if c is the number of tori and Klein bottle boundary components of N, then we will show that the dimension of $\mathcal{W}$ is $2k + c$. Note that a normal surface is always closed, but may be immersed or have branch points.

Before giving a definition of spun normal surfaces, we make some preliminary remarks about ideal vertex linking surfaces. For simplicity, in this paper we are only dealing with the case of manifolds with either boundary tori or Klein

bottles or both. However much of what is done can be carried over to the case of higher-genus boundary surfaces and we will return to this topic in a later paper.

If M is the interior of a compact manifold with boundary tori and Klein bottles, with an ideal triangulation Γ, then we will denote by T an ideal vertex linking torus or the orientable double cover of an ideal vertex linking Klein bottle. For a given homology class of a simple closed curve on T, we will choose a representative closed curve C_T with minimal length in the 1–skeleton of T, which is viewed as a normal surface constructed from triangular disk types in Γ. There is a uniquely defined infinite cyclic covering space of T corresponding to the subgroup of $\pi_1(T)$ generated by the homotopy class of C_T. Let $\widetilde{C}$ denote a lift of C_T to this covering space. Although C_T may not be simple, since it has been chosen to have minimal length, it is easy to see that $\widetilde{C}$ is a simple closed curve. So we find two half-open infinite annuli bounded by $\widetilde{C}$, which are each covered by lifted triangular disk types from T. Let A_+, A_- denote the images of these annuli, viewed as half-open infinite spiralling annuli in M. Note these annuli have boundary the curve C_T. For convenience, we label the tori boundary components and the orientable double covers of the Klein bottle boundary components of M by T_j, for $1 \leq j \leq c$, and choices of simple closed curves in T_j, for j fixed, by $C^i{}_{T_j}$, where $1 \leq i \leq m_j$.

Our definition of spun normal surfaces follows the spirit of Thurston, emphasizing the geometric picture in the 3–manifold M. However for calculations and applications, it turns out to be more convenient to use Q–theory as discussed below.

Figure 1: Spun normal surface

Definition 1.1 Suppose that M is the interior of a compact manifold with tori or Klein bottle boundary components and Γ is an ideal triangulation of M. A spun normal surface S has infinitely many normal disk types, of which

finitely many are quadrilaterals and infinitely many are triangular. Moreover S has a finite collection of boundary slopes, which are choices of closed curves $C^i{}_{T_j}$ as above, in the 1–skeleton of each boundary torus component T_j of M, or in the orientable double cover T_j of any Klein bottle component. We can glue together all except a finite number of the triangular disk types in S to form a finite collection of half open spiralling annuli $A^{ij}{}_+$ or $A^{ij}{}_-$ as described above. Then the remaining finitely many quadrilateral and triangular disk types satisfy the compatibility equations, together with this finite collection of annuli which are viewed as having boundary curves given by the normal arc types of the curves $C^i{}_{T_j}$.

Figure 2: Extra or cancelling infinite half open annuli

Notice that we can have 'extra' or cancelling infinite half-open annuli at the same boundary component of M, since if a spun normal surface S has copies of both A_+ and A_- for a given boundary slope, then we can find a new spun normal surface or possibly just a normal surface S', by removing (or cancelling) these two annuli from S. Moreover S might be embedded, immersed or have branch points. In the fifth paper of our sequence, it will be natural to consider also higher genus boundary surfaces for M. In that case, we must consider generally immersed spiralling annuli A_+, A_-, as occur in the case of Klein bottle boundary components. These arise naturally, by projecting embedded annuli in a suitable covering space of a boundary surface S, to M.

It will be very convenient to extend our ideas of normal and spun normal surfaces, to allow negative numbers of triangular and quadrilateral disk types. For normal surfaces, this is easy; we just take all integer solutions of the compatibility equations and call these formal normal surfaces, to allow coordinates (multiples of the disk types) to be any integers, not just non-negative ones. For spun normal surfaces we can play the same game by allowing the half open annuli to occur with negative multiplicity as well as the disk types and have formal solutions of the compatibility equations as well. We will refer to these

as formal spun normal surfaces.

Now to form a vector space $\mathcal{W}$ of formal spun and ordinary normal surfaces S, we will consider only the quadrilateral coordinates of each S. So $\mathcal{W}$ will be a subspace of $\mathbb{R}^{3k}$. This idea has been studied previously in [19], in case of ordinary normal surface theory in standard triangulations and is called Q–normal surface theory. For spun normal surfaces, Q–theory has been investigated in [10],[11]. There are k compatibility equations for the quadrilaterals and we discuss this in detail later on. In an ideal triangulation, the solutions to these equations are naturally either normal or spun normal surfaces. The only surfaces which are not 'seen' by this theory, are multiples of the boundary Klein bottles and tori, formed entirely of triangular disk types. If we added these in also, the theory would have dimension $2k + 2c$. However these boundary surfaces play no important role, so it is reasonable to leave them out of consideration. Spun normal surface theory has been used in an interesting way by Stefan Tillmann [18], to study essential splitting surfaces arising from representation varieties in Culler–Shalen theory.

In our fifth paper, we will prove an extension of an unpublished result of Thurston, namely that any immersed essential surface is homotopic to a spun normal surface, unless the surface lifts to a fibre of a bundle structure in some finite sheeted covering space. Consequently, if a certain boundary slope is not in the image of the boundary map (as in the examples in section 5 below) then either there are no immersed essential surfaces with such a boundary slope (in the homological sense of our boundary map), or any such a surface must be a virtual fibre.

Note that for the examples of the figure–8 knot complement and the Gieseking manifold in this paper, we are not able to get any interesting information on the boundary slopes of their immersed incompressible surfaces. These two examples are instances of layered triangulations of bundles, and the latter give special problems for the question of homotoping immersed incompressible surfaces to be spun normal. Full details are in the fifth paper.

2   The canonical basis for normal surface theory

In this section, we will construct a very useful 'canonical basis' for the solution space $\mathcal{V}$ of the compatibility equations for formal normal surface theory. This is independent of the details of the triangulation and the 3–manifold and was inspired by ideas of Casson, although he never stated a result like this. The

theorem plays a key role in the second paper in our sequence, where we study the problem of deforming taut structures on ideal triangulations to angle structures.

Theorem 2.1 *Let M be a 3–manifold with a triangulation Γ which is either ideal or not, depending on whether M is the interior of a compact manifold N with tori and Klein bottle boundary components, or M is closed. Assume there are k tetrahedra and e edges in Γ. Then $\mathcal{V}$ has a basis consisting of k formal 'tetrahedral' surfaces and e formal 'edge' surfaces.*

Proof The idea is to study e linear functionals $\phi_1, \phi_2, ..., \phi_e$ from $\mathbb{R}^{7k}$ to $\mathbb{R}$, one for each edge $E_1, E_2, ..., E_e$ of Γ. Each of these functionals restricts to $\mathcal{V}$ and we obtain e linearly-independent functionals, which will be denoted by the same symbols. It then follows that $\mathcal{V}$ splits as a direct sum $\mathcal{A} \oplus \mathcal{B}$, where $\mathcal{A}$ is the common kernel of all the linear functionals and $\mathcal{B}$ is a 'natural' cokernel. We will then find bases of $\mathcal{A}, \mathcal{B}$ separately and these will form our canonical basis.

For an edge E_i, let d_i denote its degree, ie the number of copies of edges of tetrahedra which are glued together to form E_i. For every normal triangle or quadrilateral with n vertices on E_i, we map this normal disk type to $\frac{n}{d_i}$. Extending by linearity gives a linear functional ϕ_i from $\mathbb{R}^{7k}$ to $\mathbb{R}$. To show these linear functionals restricted to $\mathcal{V}$ are linearly independent, we construct a collection of vectors $\beta_1, \beta_2, ..., \beta_e$ in $\mathcal{V}$, so that $\phi_i(\beta_j) = -2\delta_{ij}$, where as usual $\delta_{ij} = 0$ if $i \neq j$ and $\delta_{ii} = 1$. This will also show that $\beta_1, \beta_2, ..., \beta_e$ is a basis for $\mathcal{B}$ as required. We call these vectors 'edge' solutions.

Consider the collection of triangular disk types which have at least one vertex on an edge E_i. We take $-n$ copies of each such a triangular disk, where the disk has precisely n vertices on E_i, for $1 \leq n \leq 3$. Similarly consider the set of tetrahedra which contain at least one edge which becomes E_i after the faces and edges are glued together. Suppose $ABCD$ represents such a tetrahedron before gluing and AB is an edge which becomes E_i. Then one copy of the quadrilateral separating AB from CD is selected. Notice that if the edge CD also becomes E_i, then we must choose two copies of this quadrilateral. Do this for the d_i edges of tetrahedra which are glued together to form E_i. Then β_i is defined as this collection of negative triangular disks and positive quadrilateral disks.

We need to check that β_i is indeed in $\mathcal{V}$, ie is a solution of the compatibility equations. This is straightforward – consider a face ABC of a tetrahedron $ABCD$, where AB is identified with E_i. For the normal arc type running

between AC and AD, there is a triangular disk (cutting off A) and a quadrilateral disk (separating AB and CD) which are 'glued' along this arc. Notice the triangular disk is taken with sign -1 whereas the quadrilateral is taken with a positive sign. Hence the boundary arc types cancel out as required by the compatibility equations. Assume next that the tetrahedron $A'B'C'D'$ is glued to $ABCD$ by identifying ABC with $A'B'C'$. For the normal arc type running between AB and AC, the triangular disk type cutting off A' is glued to the triangular disk cutting off A, along this arc. Since both disks have sign -1, the boundary arcs cancel. Finally, a similar argument applies for the normal arc type running between AC and BC by gluing two quadrilateral disk types, separating AB and CD (respectively $A'B'$ and $C'D'$) in the two tetrahedra. One can check that self-identification of tetrahedra does not affect this cancellation and so β_i is a 'formal' normal surface, ie a solution of the compatibility equations. If there are no tetrahedra with two or more edges identified to E_i, the surface β_i can be visualized as a cylindrical box with negative top and bottom and positive sides.

Next we observe that $\phi_i(\beta_j) = -2\delta_{ij}$. It is clear that $\phi_i(\beta_i) = -2$. If there are no tetrahedra with two or more edges identified to E_i, then the functional ϕ_i takes values -1 at the top and bottom ends of the box and 0 at all other vertices. So the total value of $\phi_i(\beta_i)$ is -2 as claimed. Again one can check that self-identifications do not affect this calculation. It remains to show that $\phi_j(\beta_i) = 0$ if $i \neq j$. (We have interchanged i, j to use our previous description of the solution β_i). With notation as in the previous paragraph, assume that the edge E_j is AC. Now there are two triangular disks with signs -1 and two quadrilateral disks with signs $+1$ coming from β_i, at this edge, so their contributions to $\phi_j(\beta_i)$ cancel out. Self-identifications will not alter this phenomenon and so we have proved both that the surfaces $\beta_1, \beta_2, ..., \beta_e$ are linearly independent and also that they form a basis for a cokernel $\mathcal{B}$ for the linear functionals $\phi_1, \phi_2, ..., \phi_e$ on $\mathcal{V}$.

To complete the proof of this theorem, we need to construct a basis $\alpha_1, \alpha_2, ..., \alpha_t$ for the kernel $\mathcal{A}$ of the linear functionals. Again let $ABCD$ denote the ith tetrahedron. Then α_i will be each of the 4 triangular disk types cutting off a vertex taken with sign -1 and each of the 3 quadrilateral disk types with sign $+1$ in this tetrahedron. We must check that α_i is in $\mathcal{V}$, ie solves the compatibility equations. This is very similar to the previous argument - for a normal arc type between edges AB and AC, the triangular disk cutting off A has sign -1 and the quadrilateral disk separating AB and CD has sign $+1$, so the two boundary arcs coming from these disks cancel as required.

It is equally easy to see that all the surfaces $\alpha_1, \alpha_2, ..., \alpha_t$ are in the common

kernel $\mathcal{A}$ of the linear functionals and that they are linearly independent, since they have no non-zero coordinates in common. The final step is to prove that these surfaces span $\mathcal{A}$. So we need to consider any vector S which is in $\mathcal{A}$ and show it is a linear combination of $\alpha_1, \alpha_2, ..., \alpha_t$. Notice that the 'intersection number' of S with every edge is zero, since S is in $\mathcal{A}$. If as usual, $ABCD$ is the ith tetrahedron of Γ, then the compatibility equations into a neighboring tetrahedron $A'B'C'D'$, where the face ABC is glued to $A'B'C'$, show that the total number N (which can be positive or negative) of triangle and quadrilateral disks in $ABCD$ which meet AB is the same as the total number of triangle and quadrilateral disks in $A'B'C'D'$ which meet $A'B'$. Following the tetrahedra around the edge E_i, which is AB and $A'B'$ after identifications, we see this number N is independent of the tetrahedron containing an edge identified to E_i. Since the value of the functional ϕ_i is exactly Nd_i, where d_i is the degree of E_i, it follows that $N = 0$, since S is in $\mathcal{A}$. It is an easy exercise to check that the only sets of numbers of triangles and quadrilaterals in $ABCD$ which satisfy this condition for each of the 6 edges of the tetrahedron, are multiples of α_i. Hence this proves that $\alpha_1, \alpha_2, ..., \alpha_t$ span $\mathcal{A}$ and the construction of the canonical basis is complete. □

Remarks For ideal triangulations, where the 3–manifold M is the interior of a compact 3–manifold with tori and Klein bottle boundaries, a simple Euler characteristic argument, using Poincaré duality, shows that $k = e$, ie the number of tetrahedra is equal to the number of edges. This is the case of most interest to us. Another important case is a triangulation of a closed 3–manifold with a single vertex [9]. Again a simple Euler characteristic argument shows then that $e = k + 1$. So we conclude that the dimension of $\mathcal{V}$ is either $2k$ or $2k + 1$ respectively in these two standard cases.

3 Dimension of spun and ordinary normal surface theory

In this section, we will give a lower bound on the dimension of formal spun normal surface theory, working with an ideal triangulation of M. We begin with a quick summary of Q–normal surface theory ([19], [10], [11]). Let $m_1, m_2, ..., m_{3k}$ denote the number of quadrilateral normal disk types in an ordinary or spun normal surface. It is not hard to show that once the quadrilateral disks are specified, a formal normal or spun normal surface can be reconstituted, up to multiples of the boundary Klein bottles and tori. The key fact we need is that

the quadrilaterals satisfy $k = e$ compatibility equations, one for each edge of Γ. These equations are readily found by eliminating the triangular coordinates from the ordinary compatibility equations in the previous section. Before introducing these equations, we note an important way of labelling the corners of the quadrilateral disk types, assuming that M is orientable.

Let $ABCD$ and $A'B'C'D'$ be tetrahedra which are glued along the faces ABC and $A'B'C'$. Let AB and $A'B'$ be identified with the ith edge E_i of Γ. For the quadrilateral separating AC and BD, we will associate corner signs, $+$ to the corners on AB, CD and $-$ to corners on AD, BC (see Figure 3). Similarly for the quadrilateral separating AD and BC, $+$ is given to the corners on AC, BD and $-$ to corners on AB, CD. In the adjacent tetrahedron $A'B'C'D'$, the signs are reversed. So for the quadrilateral separating $A'C'$ and $B'D'$ (respectively $A'D'$ and $B'C'$), we will associate corner signs, $-$ to the corners on $A'B', C'D'$ (respectively $A'C', B'D'$) and $+$ to corners on $A'D', B'C'$ (respectively $A'C', B'D'$) (see Figure 3). To show that this assignment of signs is consistent for all quadrilaterals simultaneously, we note that it is equivalent to introducing an orientation on each tetrahedron. For example, a right handed rule on the tetrahedron $ABCD$ can be viewed as having orientations from A to B on the edge AB and then circulating from the face ABD to the face ABC so that the normal arc running between AB and AD cutting off A is transformed into the normal arc running between AB and BC cutting off B in the quadrilateral separating AC and BD (see Figure 3).

Figure 3: Labelling the corners of quadrilateral disk types

We associate this with the positive sign in the corner of the quadrilateral at the corner on AB. It is easy to see that if the orientation of AB is reversed, we still

have a positive sign at this corner coming from the right hand rule. By translating a right handed system throughout M, we see that the consistency of signs is guaranteed. Now for an orientable manifold, we can define a quadrilateral compatibility equation by taking the sum of all quadrilateral types meeting a fixed edge E_i with sign given by the corner of each quadrilateral at E_i. So half the quadrilaterals have sign $+$ and half have sign $-$.

On the other hand if M is non-orientable, then choosing an orientation reversing loop passing through centers of tetrahedra and faces, following around the quadrilaterals in these tetrahedra will give an inconsistency in this choice of corner signs. However we can still give a sign to corners of quadrilaterals around each fixed edge E_i, but cannot do this consistently for all edges and corners simultaneously. We do obtain a similar compatibility equation in the non-orientable case, since it does not matter how the quadrilateral corner signs vary from one edge to the other.

We are now ready to give the main result of this section.

Theorem 3.1 *Let M be the interior of a compact manifold with boundary components which are tori or Klein bottles. Let Γ denote an ideal triangulation of M and let $\mathcal{W}$ be the vector subspace of formal normal and spun normal surfaces. Then the dimension of $\mathcal{W}$ is at least $2k + c$, where k is the number of edges in Γ and c is the number of boundary components.*

Proof We first show that there is at least one redundancy in the set of Q–matching equations, if M is orientable. For adding all the equations, each quadrilateral appears in at most 4 equations with a total of exactly two $+$ signs and two $-$ signs. Consequently the entries corresponding to this quadrilateral will cancel, ie the sum of all Q–matching equations is zero. This proves that we need at most $k - 1$ matching equations and the dimension of $\mathcal{W}$ is at least $2k + 1$.

The next step is to analyze the case when there is more than one boundary torus, supposing that M is orientable. So there are several ideal vertices, $V_1, V_2, ..., V_c$. Now label any tetrahedron $ABCD$ by specifying which ideal vertices are identified with A, B, C, D. Let us consider first the case that there are only two ideal vertices V_1, V_2 (see Figure 4). There are 5 cases, depending on how many of the vertices A, B, C, D are labelled V_1. We prove that adding all the matching equations corresponding to edges with both ends labelled V_1 gives the same result as adding over all edges with both vertices at V_2. So there is a second redundancy in the matching equations and the dimension of $\mathcal{W}$ is at least
$$\sum \varepsilon(V_1V_1)=0 \qquad \sum \varepsilon(V_1V_1)=0 \qquad \sum \varepsilon(V_1V_1)= \sum \varepsilon(V_2V_2) \qquad \sum \varepsilon(V_2V_2)=0$$

Figure 4: The cases of two ideal vertices

$2k+2$. Note that if the number $n \neq 2$ of vertices in some tetrahedron which are labelled V_1, then adding the appearances of a quadrilateral type in this tetrahedron over all matching equations corresponding to edges with both ends at V_1 will give zero. This is because the signs at the corners of the quadrilateral at such edges always cancel. For the final case of two vertices labelled V_1 and two labelled V_2, we see that the number of appearances of a quadrilateral type in the two sums of matching equations is the same. Consequently this case is complete.

Generally, if there are ideal vertices, $V_1, V_2, ..., V_c$, then we find (by the same argument) that the sum of the matching equations at edges labelled V_1V_1 is equal to the sum of the matching equations at all edges labelled V_iV_j for $i, j > 1$ and similarly for $V_2V_2, ..., V_cV_c$. Note that by connectivity of the one-skeleton of Γ, we have paths of edges between any two ideal vertices. This is easily seen to imply that there are at least $c-1$ such redundant matching equations and one redundancy that the sum of all Q–matching equations is zero. Hence the dimension of $\mathcal{W}$ is at least $2k+c$. In fact, one can consider a collection of variables labelled x_{ij}, one for each equation which is a sum of the compatibility or matching equations at all edges labelled V_iV_j. Then our relations found above can be written as $x_{mm} = \Sigma\{x_{ij} : i, j \neq m\}$ for $m = 1, 2, \ldots, c-1$ and $\Sigma x_{ij} = 0$. Now it is easy to put this system of linear equations into row-echelon form and check that the rank is indeed c, proving that there are at least c redundant compatibility equations.

Assume next that M is non-orientable. Let $\widetilde{M}$ denote the orientable double cover of M with $\widetilde{\Gamma}$ the lifted triangulation. There are pairs of edges interchanged by the covering involution σ. We are interested in vectors of quadrilaterals which are invariant under the induced action of σ, since any lifted normal or spun normal surface will lift to such a vector. So we introduce $3k$ new independent variables, by forming a copy of $\mathbb{R}^{3k}$ embedded in $\mathbb{R}^{6k}$, given by

$\alpha \to (\alpha, \sigma(\alpha))$ for a vector α in $\mathbb{R}^{3k}$. Our matching equations can be thought of as being located around two edges $E, \sigma(E)$ simultaneously. This is achieved by using the new variables, which are integer multiples of pairs of quadrilateral disks $(D, \sigma(D))$. As σ reverses orientation, it must reverse our choice of signs of corners of quadrilateral disks in $\widetilde{M}$. Hence corresponding quadrilateral coordinates in $\widetilde{M}$ under the induced action of σ are negatives of each other, ie $n(D, \sigma(D))$ corresponds to the pair of coordinates $(n, -n)$ in $\widetilde{M}$.

The conclusion is that we do get a similar theory to the orientable case, starting with k matching equations and finding c redundancies, proving the dimension estimate is also valid in the non-orientable case. Note that c is the number of Klein bottle and tori boundary components of M, since each Klein bottle lifts to a torus which is invariant under σ and a torus lifts to a pair of tori interchanged by σ. So since invariant boundary components or pairs of switched components give rise to redundancies, this is the correct definition of c.

To illustrate this, consider the simple case that M has a single boundary component which is a Klein bottle or torus. This lifts to a σ–invariant torus or a pair of tori interchanged by σ in $\widetilde{M}$. We can label the ideal vertex or vertices by this torus or tori. The single relation amongst our new pairs of quadrilateral coordinates becomes just that the sum of all the matching equations is zero. If there were more boundary components, then an analogous argument to the previous one shows that there is at least one redundancy amongst the matching equations of the pairs of quadrilateral coordinates for each boundary component of M.

Next, if there are two boundary components of M, then we get two classes of ideal vertices of $\widetilde{M}$. Each class is either a single vertex which is fixed under the action of σ or a pair of vertices interchanged by σ. As previously, it is easy to check with our new coordinates, that the sum of all the matching equations for edges with both ends in one vertex class gives the same result as the sum over all edges with both ends in the other class. The general case follows the same pattern as before. □

4 The boundary map for spun normal surface theory

To complete the computation of the dimension of $\mathcal{W}$, we need to prove it is also bounded above by $2k + c$. To do this, we will define a boundary map $\partial \colon \mathcal{W} \to \mathbb{R}^{2c}$, where the range of ∂ is the direct sum of all the homology groups $H_1(T_i, \mathbb{R})$, where the T_i are the tori boundary components or the orientable double covers

of the Klein bottle boundary components of M, for $1 \leq i \leq c$. A key property of ∂ is that its kernel A is precisely the quadrilateral vectors corresponding to all formal normal surfaces in $\mathcal{W}$. Hence we can compute readily the dimension of A as $2k - c$, since the natural projection $\mathcal{V} \to \mathcal{W}$, which erases the triangular coordinates of a normal class, has kernel generated by the boundary tori and Klein bottles, so has dimension c. Since the dimension of $\mathcal{V}$ is $2k$, we will see that the subspace A of standard normal classes in $\mathcal{W}$ has dimension $2k - c$. Consequently, the dimension of $\mathcal{W}$ is at most $2k - c + 2c = 2k + c$ and the computation of dimension will be complete. Moreover we obtain the important result that ∂ has image of dimension $2c$, so maps onto a subgroup of finite index, when using $\mathbb{Z}$ coordinates. We compute the image of ∂ for the figure–8 knot space and Gieseking manifolds in the final section.

Theorem 4.1 *Let M be the interior of a compact manifold with boundary components which are tori or Klein bottles. Let Γ denote an ideal triangulation of M and let $\mathcal{W}$ be the vector subspace of formal normal and spun normal surfaces. Then the dimension of $\mathcal{W}$ is $2k + c$, where k is the number of edges in Γ and c is the number of boundary components. Moreover the boundary map $\partial \colon \mathcal{W} \to \mathbb{R}^{2c}$ is onto and hence when using $\mathbb{Z}$ coefficients, it follows that ∂ has image of finite index in the direct sum $\mathbb{Z}^{2c}$ of the homology groups $H_1(T_i, \mathbb{Z})$, where the T_i are the tori boundary components or the orientable double covers of the Klein bottle boundary components of M, for $1 \leq i \leq c$.*

Proof As in the previous section, we begin with the case that M is orientable, so we can put signs on all corners of quadrilateral disks in a consistent manner. We will then proceed to put orientations on all boundary arcs of quadrilaterals. As previously, let $ABCD$ denote a tetrahedron and consider the quadrilateral separating edges AC and BD. Assume that a $+$ sign is attributed to the vertex on the edge AB as in the previous section. We now orient the boundary arc of this quadrilateral running between the vertices u, u' on AB, AD respectively with an arrow from u to u' (see Figure 5). If v, v' are the vertices on the edges BC, CD respectively, then the boundary edges are oriented in the directions $v'v, uv, v'u'$, ie from a vertex of $+$ sign to a vertex of $-$ sign. Notice that if we adopt the convention that a triangular face has the tetrahedron behind it, with a normal boundary arc having the vertex cut off above it and the positive corner is on the left and the negative on the right, then the orientation of the arc is from left to right. All 4 arcs are now oriented the same way by this convention, as are all arcs of all quadrilaterals.

Next we want to glue together quadrilaterals at corner vertices and possibly along some boundary arcs. Imagine two 'adjacent' quadrilaterals with such a
Figure 5: Orientation of the boundary arcs of a quadrilateral

vertex in common at some edge of Γ, eg the corner u at the edge AB in the previous paragraph for the first quadrilateral, chosen so that there is a wedge of triangular disks at u between these two quadrilaterals on a (possibly spun) normal surface S. There could be an empty wedge, if these two quadrilaterals are actually glued along an edge, eg the edge uu', rather than just glued at the corner vertex u. Now it is easy to see the sign of the corner of the second quadrilateral at u must be $-$, ie the signs of the two adjacent quadrilaterals at such a vertex are always opposite. So we proceed to glue together quadrilaterals with vertices on the same edge of Γ with opposite signs at these vertices.

Notice by the compatibility equations for quadrilaterals, eventually at u we find an even number of quadrilaterals with alternating signs glued together in this fashion. Do this for all vertices of all quadrilaterals in any formal vector of quadrilaterals in $\mathcal{W}$. We call this the quadrilateral part of the surface and denote it by S_Q. There are finitely many ways of producing a quadrilateral part of a normal surface, which can then be filled in by triangular disks to form S. If the boundary curves of S_Q are inessential on the boundary tori of M, then we can complete S using disks and once-punctured tori, and obtain a closed normal surface. If these curves are essential, we get a spun normal surface. See [10], [11] for further details on this.

Now the key point is that since our choice of orientations of boundary arcs is independent of the gluings, and when two quadrilaterals are glued along such an arc, then the two orientations cancel, we see that the total homology class of the boundary curves of S is independent of the choice of gluing of S. Therefore we have proved that there is a well-defined map $\partial\colon \mathcal{W} \to \mathbb{R}^{2c}$ from a normal class in $\mathcal{W}$ to a boundary homology class in the first homology of the boundary tori. As there are assumed to be c boundary tori, the image is in $\mathbb{R}^{2c}$ as claimed.

It is possible to have a situation where this boundary homology class is zero but the surface S is spun normal, for example if there are two essential parallel curves C, C' in the boundary of a core of S and the surface is spinning around a boundary torus in opposite directions from C, C'. It is easy to see that this cannot happen for an embedded surface S, but in the general case of singular surfaces, such behaviour cannot be ruled out. However we can cut off the two infinite half-open annuli of triangular disks in S and replace by a compact annulus of triangular disks joining up C, C' to form a normal surface, which is no longer spun. This illustrates the general fact that the kernel of ∂ consists of classes which can be represented by standard normal surfaces.

To prove this, if there are several curves $C_1, ..., C_m$ in the boundary of a core of S and the sum of the homology classes of these curves is zero, then we can fill in the curves by a cycle consisting of triangles in the boundary tori of M. This may be a singular choice, since the curves might intersect. The cancelling of the signs corresponds to the normality of the resulting possibly singular closed surface.

In the non-orientable case, we proceed in a similar manner to the previous section. Let $\widetilde{M}$ be the orientable double covering with covering transformation σ and lifted triangulation $\widetilde{\Gamma}$. Any spun normal surface lifts to a σ–invariant surface or a pair of such surfaces in $\widetilde{M}$. Now the boundary map $\widetilde{\partial}$ takes such a surface or pair of surfaces to a σ–invariant homology class in the boundary tori of $\widetilde{M}$. Hence we can project this to a corresponding class in the boundary tori and Klein bottles of M, and hence define the boundary map in M. For a pair of tori interchanged by σ this is easy, since we have a pair of homology classes in the tori which are the two lifts of a single class in a boundary torus of M. For a single σ–invariant torus covering a Klein bottle, a σ–invariant homology class or pair of classes interchanged by σ, both project to a homology class in the Klein bottle. Notice that the boundary of a spun normal surface is always a 2–sided curve, since it is the end of a half open annulus with infinitely many triangles projecting to a torus or Klein bottle. So we can again use $\mathbb{R}$ coefficients for convenience, without losing any information.

The argument in the introduction of this section shows that this map is onto and so using $\mathbb{Z}$ coefficients, the corresponding map has an image of finite index in $\mathbb{Z}^{2c}$.

An elegant alternative approach was suggested by the referee. When considering all possible gluings of a surface from the normal disk types, it is necessary to observe that the resulting boundary of the surface is independent of the choice of gluing. However, one can consider the sum of the oriented boundary arcs of

each quadrilateral as forming a 1–chain. Then the sum of these quadrilateral boundary arcs is the boundary of the sum of the quadrilaterals, viewed as a 2–chain, since a pair of oppositely oriented boundary arcs, coming from two quadrilaterals which may be glued along these arcs or may not, depending on the way the normal surface is formed from the disk types, will cancel out in this 1–chain. Hence the sum, which is a 1–cycle because of the matching equations and gluing rule, is independent of the choice of how the quadrilaterals are glued up. □

In the final section we examine ∂ with $\mathbb{Z}$ coefficients more closely, for the simplest interesting orientable and non-orientable examples.

5 The figure–8 knot complement and the Gieseking manifold

In the previous section, we defined the boundary map $\partial\colon \mathcal{W} \to \mathbb{R}^{2c}$ and showed that it has rank $2c$. Here the figure–8 knot complement is presented as an example for which the boundary map is not onto, using $\mathbb{Z}$ coefficients. Also we describe the Gieseking manifold as a non-orientable example.

Figure 6 shows an ideal triangulation of the figure–8 knot complement described by Thurston [17]. It has two tetrahedra, two edges and one torus cusp. Following the argument in the previous section, the vector space $\mathcal{W}$ of spun and ordinary normal surfaces in the figure–8 knot complement has dimension 5. Define the boundary map $\partial\colon \mathcal{W} \to \mathbb{R}^2$ described in section 4. We compute the total homology classes of some normal surfaces which imply that the boundary map is not onto. For each tetrahedron in Figure 6, we have three types of quadrilaterals denoted by Q_1, Q_2 and Q_3 in T and Q'_1, Q'_2 and Q'_3 in T' (see Figure 7). Using the right hand rule, we give signs of corners of the quadrilaterals as in Figure 7.

Let x_i and y_i denote the number of quadrilaterals of Q_i and Q'_i types respectively, for $i = 1, 2, 3$. The following is the system of Q–matching equations of the figure–8 knot complement [10], for the two edges of the triangulation. As in Section 3, the sum of these two equations is zero, ie one of the two equations is redundant.

$$\begin{cases} -2x_1 + x_2 + x_3 - 2y_1 + y_2 + y_3 = 0 \\ 2x_1 - x_2 - x_3 + 2y_1 - y_2 - y_3 = 0. \end{cases}$$
Figure 6: An ideal triangulation of the figure–8 knot complement

Figure 7: All quadrilateral disk types

There are twenty (possible) fundamental solutions of the system. Among those, the following six are all the different solutions up to symmetry.

$$s_1 = (1, 0, 0, 0, 0, 2),$$
$$s_2 = (1, 2, 0, 0, 0, 0),$$
$$s_3 = (1, 1, 1, 0, 0, 0),$$
$$s_4 = (1, 1, 0, 0, 1, 0),$$
$$s_5 = (1, 1, 0, 0, 0, 1),$$
$$s_6 = (1, 0, 0, 0, 1, 1).$$

It is known that the figure–8 knot complement has the symmetry group isomorphic to the dihedral group

$$D_4 = \langle f, h | f^4 = h^2 = 1, h \circ f \circ h^{-1} = f^{-1} \rangle.$$

So all the other fundamental solutions can be obtained by isometries in D_4. We will show that all the normal surfaces corresponding to the above six solutions have boundary with an even number at the first component of the total homology class. This will imply that the normal surfaces corresponding to all the other fundamental solutions have also such boundary curves. Hence the boundary map has image with only even numbers at the first component, so is not onto. (Our convention will be that the meridian curve will have homology class $(1, 0)$ and the longitude will correspond to $(0, 1)$ for suitable orientations, as described below).

We label the vertices of the ideal tetrahedra of the figure–8 knot complement as shown in Figure 6. Then the symmetries f and h can be represented by the following permutations of the eight vertices;

$$f = (1234)(5876) \quad \text{and} \quad h = (15)(26)(37)(48)$$
Figure 8: All arc types

Table 1 shows the transformations of arc types in Figure 8 by the symmetries f and h. The letter label of each arc type is given by the label of the face containing the arc type with subscript label being the vertex cut off by the arc type.

Let S be the spanning once-punctured torus for the knot which has the boundary curve $A_1 C_2 B_3 D_4$ as shown in Figure 9. We let, for convenience, $L =$

	A_1	A_2	A_4	B_2	B_3	B_4	C_1	C_2	C_3	D_1	D_3	D_4
f	C_2	C_3	C_1	D_3	D_4	D_1	B_2	B_3	B_4	A_2	A_4	A_1
h	A_5	A_6	A_8	B_6	B_7	B_8	D_5	D_6	D_7	C_5	C_7	C_8

	A_5	A_6	A_8	B_6	B_7	B_8	C_5	C_7	C_8	D_5	D_6	D_7
f	C_8	C_5	C_7	D_5	D_6	D_7	B_8	B_6	B_7	A_8	A_5	A_6
h	A_1	A_2	A_4	B_2	B_3	B_4	D_1	D_3	D_4	C_1	C_2	C_3

Table 1: Transformations of arc types by f and h

$A_1 C_5 B_3 D_7$ be the curve going (homotopically) around the longitude of the torus cusp once so that it has the homology class $(0, 1)$ (see Figure 9). Notice that the orientation of the boundary arcs of each quadrilateral is given in section 4 so that the orientation of the boundary curves of a quadrilateral surface S_Q is also fixed automatically. From the table, we can see that L is transformed to the curve $C_2 B_8 D_4 A_6$, which also goes (homotopically) around the longitude once, by the symmetry f. By the symmetry h, L is transformed to $A_5 D_1 B_7 C_3$, which traverses the longitude (homotopically) in the opposite direction to L. $M = A_4$ is a curve going (homotopically) around the meridian with homology class $(1, 0)$ and it is transformed to C_1 by f, and to A_8 by h. Hence the homology class of the meridian is preserved by both symmetries, but we need to determine whether its orientation is preserved or reversed. To do this, consider the curve $D_1 D_4 C_3 C_1$ which follows (homotopically) the longitude once in the negative orientation and the meridian 2 times in the negative orientation (see Figure 9), This curve is transformed to $A_2 A_1 B_4 B_3$ by f and to $C_5 C_8 D_7 D_6$, by h. In the first case, we see that the image curve winds (homotopically) around the longitude once in the negative orientation and the meridian twice in the positive orientation, whereas in the second case the curve is taken to itself (homotopically) with opposite orientation. So we conclude that f preserves the homology class of L but reverses that of M, whereas h reverses both classes. Hence both C_1 and A_8 traverse the meridian (homotopically) in the opposite direction to A_4 (see Figure 9) and have the homology class $(-1, 0)$. Also since C_1 is transformed to B_2 by f, and to D_5 by h, the homology classes of B_2 and D_5 are $(1, 0)$. It follows automatically that B_6 and D_3 have the homology class $(-1, 0)$. All the other non-trivial curves are linear combinations of the meridian and longitude.

Now we will compute the boundary curves of the spun and ordinary normal surfaces corresponding to the solutions s_1, s_2, s_3, s_4, s_5 and s_6. Since the total homology class of the boundary curves of any of the surfaces corresponding to
Figure 9: Boundary torus

a solution of the matching equations is independent of the choice of gluing, we choose our surfaces for convenience. Figure 9 is useful as a reference, when computing the boundary class. Notice that each of these solutions has Euler characteristic -1, since a quadrilateral has 'negative curvature' $-2\pi/3$, coming from its four vertices all lying on edges of degree 6. Hence we expect each of the surfaces to be either a once-punctured Klein bottle, a twice-punctured projective plane or a thrice-punctured sphere, if all the boundary curves are essential. We can cap off any inessential boundary curves by disks in the torus at the cusp.

Let F_1 be a normal surface obtained from the solution s_1. The edges of the quadrilaterals of F_1 are A_1, C_2, B_3, D_4, $2B_6$, $2A_8$, $2C_5$ and $2D_7$. We may assume that the edges C_2 and C_5, and D_4 and D_7 are glued together and

cancelled out in the boundary class. Hence the boundary of F_1 is the curve $A_8 D_7 A_1 B_6 B_6 C_5 B_3 A_8$ which has the total homology class $(-4, 1)$, ie winds once around the longitude and minus four times around the meridian (see Figure 10). Notice that as is well-known, at this slope, there is an embedded once-punctured Klein bottle, which is just the surface F_1.
Figure 10: Boundary curves of F_1

Now for the solution $s_2 = (1, 2, 0, 0, 0, 0)$, a normal surface F_2 corresponding to s_2 has the following three boundary components; $A_2 B_3 B_4 A_1$, $C_1 C_1 D_4 B_4$, and $D_3 D_3 C_2 A_2$ which have the homology classes $(-2, 1)$, $(-1, 0)$ and $(-1, 0)$, respectively (see Figure 11). Hence the total homology class of the boundary curves of F_2 is $(-4, 1)$. F_2 must be an immersed thrice-punctured sphere.

Let F_3 be a normal surface corresponding to the solution s_3. We can choose the gluing so that F_3 has the boundary curves $A_1 D_1 B_2$, $B_4 D_4 C_1$, $B_3 C_3 A_4$ and $A_2 C_2 D_3$, all of which have the homology class (0,0) (see Figure 12). After capping off the trivial curves, this is a tetrahedral surface of the canonical basis defined in the section 2. Notice that the surface has branch points. Actually there is no gluing for an immersed normal surface corresponding to the solution s_3.

Let F_4 be a normal surface corresponding to the solution $s_4 = (1, 1, 0, 0, 1, 0)$. We choose F_4 to have the boundary curves $B_4 C_1 D_4$ and $C_2 A_6 C_7 A_1 A_2$ which have the homology classes $(0, 0)$ and $(2, 0)$, respectively (see Figure 13). Hence the total homology class is $(2, 0)$. As the case of s_3, there is no corresponding immersed normal surface to the solution s_4.
Figure 11: Boundary curves of F_2

Figure 12: Boundary curves of F_3

For the solution $s_5 = (1, 1, 0, 0, 0, 1)$, a corresponding normal surface F_5 has the boundary curves $A_2 B_3 A_8 D_7 A_1$, $B_4 D_4 C_1$, B_6 and D_3. The homology classes of the curves are $(-2, 1)$, $(0, 0)$, $(-1, 0)$ and $(-1, 0)$ and the total homology class is $(-4, 1)$ (see Figure 14). After capping off the trivial curve, this is an immersed thrice-punctured sphere.

Finally for the solution $s_6 = (1, 0, 0, 0, 1, 1)$, we can choose a normal surface F_6 which has boundary curves A_8, B_6, C_7 and D_5. Then the homology classes
Figure 13: Boundary curves of F_4
Figure 14: Boundary curves of F_5

of the curves are $(-1,0)$, $(-1,0)$, $(1,0)$ and $(1,0)$, respectively and the total homology class of the boundary curves of F_6 is $(0,0)$ (see Figure 15). In this case, the surface has a branch point. Notice that there is no gluing for an immersed normal surface corresponding to the solution s_6.

Therefore all six solutions correspond to normal surfaces which have even numbers at the first component of the total homology class of the boundary curves. Since the normal surfaces corresponding to the other fundamental solutions

are obtained from the normal surfaces corresponding to these six solutions by symmetries, and the symmetries transform the boundary curves as shown previously, the total homology classes of the boundary curves of any spun normal surfaces in the figure–8 knot complement have only even numbers at the first component. Hence the boundary map $\partial\colon \mathcal{W} \to \mathbb{R}^2$ has image the subgroup of index 2 consisting of all slopes of the form $(2m, n)$.
Figure 15: Boundary curves of F_6

Finally we study the Gieseking manifold, which has an ideal triangulation with one tetrahedron, one edge and a Klein bottle cusp. The Gieseking manifold is double-covered by the figure–8 knot complement and has covering transformation by the symmetry $f \circ h = (18)(25)(36)(47)$. Figure 16 shows the Gieseking manifold and a fixed orientation going around the unique edge.

We denote each wedge $\widehat{1}, \widehat{2}, \widehat{3}, \widehat{4}, \widehat{5}$ and $\widehat{6}$ by $\widehat{DA}, \widehat{CD}, \widehat{BC}, \widehat{AC}, \widehat{AB}$ and $\widehat{DB}$ according to the labels of the two adjacent faces and the fixed orientation going around the edge. Since the wedges $\widehat{CD}, \widehat{AC}$ and $\widehat{DB}$ have the opposite orientations to the ones obtained by the right hand rule applied to each edge in the tetrahedron without identification (see the case of the figure–8 knot complement), the signs of corners of quadrilaterals are as shown in Figure 17. Therefore the Q–matching equation of the Gieseking manifold is

$$-2x_1 + x_2 + x_3 = 0,$$

where x_1, x_2 and x_3 are the number of quadrilaterals of type Q_1, Q_2 and Q_3,
Figure 16: Gieseking manifold

Figure 17: Signs of corners of quadrilaterals in the Gieseking manifold

respectively. Then all positive solutions are generated by the following solutions

$$t_1 = (1, 1, 1),$$
$$t_2 = (1, 2, 0),$$
$$t_3 = (1, 0, 2).$$

Now we will compute the homology class of the boundary curves of normal surfaces corresponding to each solution t_1, t_2 and t_3. We will follow exactly the same procedure as in the case of the figure–8 knot complement.

Figure 18 shows the Klein bottle cusp of the Gieseking manifold. Note that the orientation around each vertex along a column is shown in opposite directions alternately. This will assist in determining the signs of the homology classes of curves. Also we call the longitude the slope $L = A_2 A_1 B_4 B_3$, which is equivalent to the curve $A_1 D_4 B_3 C_2$, and the meridian the slope $M = B_4$ to conform to the figure–8 knot terminology (see Figure 18). Notice that B_4 lifts
Figure 18: Boundary Klein bottle of the Gieseking manifold

to $B_4 D_4$, which is homotopic to the meridian slope A_4 of the torus cusp in the figure–8 knot complement, by the double covering map from the figure–8 knot complement onto the Gieseking manifold. Let the homology classes of L and M be $(0,1)$ and $(1,0)$, respectively. Then we get the homology classes of the following curves; $A_2 \sim \overline{C_2} \sim D_4 \sim \overline{B_4}$ with $(-1,0)$, $D_3 \sim A_4 \sim \bar{D}_4 B_4$ with $(2,0)$, $A_4 \sim \overline{C_1} \sim \overline{B_2}$ with $(2,0)$, $C_3 B_3 \sim C_1 \sim B_2$ with $(-2,0)$ and $A_1 D_1 \sim A_4 \sim D_3$ with $(2,0)$.

Let G_1 be a normal surface obtained from the solution $t_1 = (1,1,1)$. We can choose G_1 to have boundary curves $D_3 C_3 B_3$, $A_4 D_4 B_4$, $C_1 D_1 A_1$ and $B_2 C_2 A_2$, all of which have the trivial homology class (see Figure 19). Hence the total homology class of the boundary curves of G_1 is $(0,0)$. Note that the curves, D_3, A_4, C_1, B_2, $C_2 D_1 D_4 C_3$ and $A_2 A_1 B_4 B_3$, are also the boundary curves of

a normal surface obtained from the same solution but by another gluing. If we examine the orientations of the curves carefully, we will see that the curves have the homology class $(2,0)$, $(2,0)$, $(-2,0)$, $(-2,0)$, $(-4,-1)$ and $(4,1)$, respectively (see Figure 20). Hence the total homology class of these boundary curves is also trivial.

Figure 19: Boundary curves of G_1

Figure 20: Boundary curves of another G_1

Next look at the solution $t_2 = (1,0,2)$. We get a normal surface with boundary curves $C_2 C_3 A_4 D_4 D_1$, $B_2 B_2$ and A_4 which have the homology classes $(2,-1)$,

$(-4, 0)$ and $(-2, 0)$, respectively (see Figure 21). Then the total homology class is $(0, -1)$. Note that the edge pairs D_1 and B_3, and C_3 and A_1 cancel out.

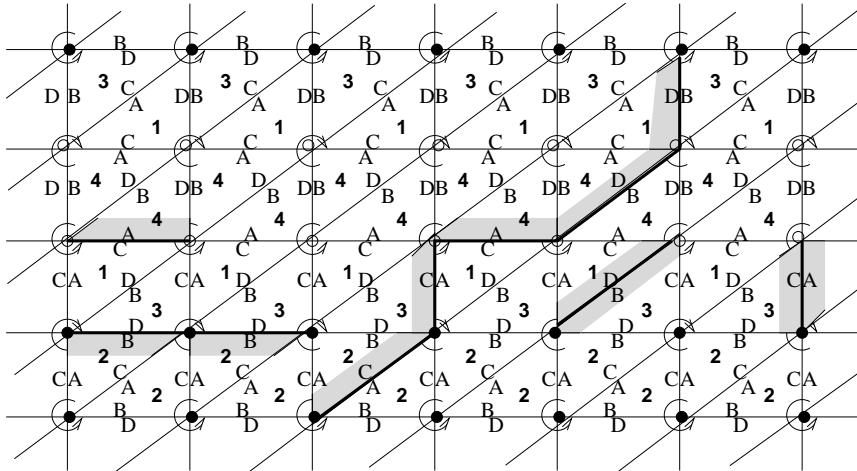

Figure 21: Boundary curves of G_2

Finally for the solution $t_3 = (1, 2, 0)$, we get the following boundary curves: $D_3 D_3 A_2 A_1 B_4 B_3$, $C_2 A_2$ and $C_1 C_1$ which have the homology class $(6, 1)$, $(-2, 0)$ and $(-4, 0)$ (see Figure 22). The edge pair D_4 and B_4 cancels out. Hence the total homology class is $(0, 1)$. Therefore as in the case of the figure–8 knot complement, the boundary map of the Gieseking manifold also has only multiples of 4 at the first component and is not onto. Note that for the first homology of the Klein bottle, the longitude is an element of order two. Hence we have found the image of the boundary map is a subgroup of index 4 of the group $\mathbb{Z} \oplus \mathbb{Z}_2$.
